DEPARTMENT OF ENVIRONMENTAL PROTECTION WATER RESOURCES MANAGEMENT NEW JERSEY GEOLOGICAL AND WATER SURVEY

INTRODUCTION

Surficial geologic data are useful for land-use planning, management of resources, contaminant remediation, and delineation of geologic resources. Surficial materials in the High Bridge quadrangle are highly variable, cover bedrock surfaces, and are found in many types of landscape settings. They weathered bedrock derived from carbonate rock, shale, sandstone, gneiss, conglomerate, that formed throughout the Quaternary and possibly during the glacial deposits, including till and glaciofluvial sand and gravel of early Pleistoc glaciofluvial sand and gravel of late Pleistocene age; 3) colluvium mostly of mip Pleistocene age; 4) fluvial terrace deposits of middle and late Pleistocene alluvium and swamp deposits of late Pleistocene and Holocene age. Surficial depicted on the map based on their physical characteristics, readily distinguishai ies, and location on the landscape. They are further delineated by genetic and criteria. Thickness is as much as 30 feet for glacial sediment, 50 feet for colluv for weathered rock, and less than 20 feet for alluvium and fluvial terrace depo	and hazards. most of the y include: 1) granite, and Neogene; 2) cene age, and iddle and late age; and 5) I deposits are able boundar- morphologic ium, 150 feet
Over the last 2.5 million years, the landscape of the map area has been shaped periods of glacial and periglacial erosion and weathering related to the growth the Laurentide ice sheet in North America. Braun (1989) estimated that the been as many as ten glaciations of a magnitude sufficient to introduce a perigl to this region. During these periods, cold temperatures enhanced the break-up a tation of rock largely by frost shattering, and mass-wasting of slope materials about by permafrost and a change to a shallow-rooted vegetative cover. Collu- weathering product of periglacial climate, was deposited where weathered to	and decay of ere may have lacial climate and fragmen- was brought vium, a major

was eroded off uplands onto the lower parts of hillslopes and onto the floors of narrow valleys and heads of drainage basins. This material was later partly eroded by streams during interglacial periods. Remnants of deposits of an early Pleistocene glaciation are found throughout the quadrangle in areas where they have been protected from mass wasting and fluvial erosion. Although the effects of glaciation in modifying the landscape are pronounced, these modifications have been largely erased in the map area by subsequent periods of periglacial erosion and deposition. Since the map area was last glaciated, streams have cut as much as 100 feet into the older landscape. This incision of the land was probably caused by the drop in sea level due to growth of ice sheets in the northern hemisphere during the early and middle Pleistocene. Flexural uplift related to Pleistocene erosion on land and sediment loading offshore may have also contributed to stream downcutting.

PHYSIOGRAPHY AND BEDROCK GEOLOGY

The High Bridge quadrangle lies mostly in the New Jersey Highlands physiographic province except for its southern part, which lies in the Piedmont physiographic province (fig. 1). The map area is a mix of rural and suburban settings, marked by patchwork woodlands, cultivated land, and larger forested areas that cover parts of the Highlands. The highest point is 1,034 feet above sea level near Woodglen, and the lowest point, approximately 178 feet above sea level, lies on the South Branch of the Raritan River (hereafter, just "South Branch") in Clinton. Major landform elements define a southwest-northeast topographic grain. Musconetcong Mountain is part of a broad upland that covers the center part of the quadrangle and Pohatcong Mountain is a narrow ridge in the northwestern corner of the quadrangle. The Musconetcong Valley separates these two uplands. South of the Highlands, the Piedmont is a rolling lowland that contains Spruce Run Reservoir.

In the Highlands, Musconetcong Mountain and Pohatcong Mountain rise between 300 and 700 feet above the valleys and are chiefly underlain by gneiss and granite of Middle Proterozoic age (fig. 2). Topography here is rugged and deeply dissected. Ridgelines generally follow layering in the gneiss and granite bedrock, although discordant trends are common. Rock outcrops are limited to a few narrow ridgetops, steep slopes, and streambanks. Elsewhere, the rock surface is covered by thick saprolite and colluvium (fig. 3). Musconetcong Valley is underlain by carbonate rocks of Cambrian and Ordovician age with some minor shale. Rock outcrops here are limited to steep riverbanks and small outcrops on flatter surfaces that are the tops of pinnacles and ridges protruding through the otherwise continuous mantle of silty clay weathering residuum (fig. 3).

The Piedmont area in the quadrangle is underlain by shale, sandstone, and carbonate rock of

Cambrian and Ordovician age, and conglomerate, sandstone, and siltstone of Triassic age. Outcrops are few and typically limited to quarries, excavations, and road and railroad cuts. Relief in the Piedmont area is less than 200 feet. The quadrangle lies mostly in the Raritan River drainage basin. The Piedmont and most of Musconetcong Mountain are in the Raritan basin and are drained by the South Branch and ts tributaries Spruce Run and Mulhockaway Creek. The northwestern third of the quadrangle is in the Delaware River basin. The northwestern slope of Musconetcong Moun-

tain and Musconetcong Valley are in the Delaware basin and are drained by the Musconetcong River, which flows southwestward through a broad valley that follows the strike of the underlying carbonate rocks. PREVIOUS INVESTIGATIONS The surficial geology of the High Bridge quadrangle and surrounding area was first

discussed by Cook (1880). He noted the distribution of quartzite boulders and scattered patches of thin gravelly drift in Musconetcong Valley. Most of this material was thought to be "modified glacial drift", possibly deposited by meltwater and reworked later by weathering and fluvial erosion. On greater inspection (Salisbury, 1894) this "modified glacial drift" was determined to be of glacial origin and called extra-morainic drift because of its distribution south of the Wisconsinan terminal moraine. Salisbury (1902) assigned the drift a Kansan age because of its deeply weathered appearance, which suggested it was the product of a glaciation that was much older than the Wisconsinan glaciation. Chamberlain and Salisbury (1906) correlated this drift to the sub-Aftonian glacial stage of Iowa, using the term "Jerseyan" as an equivalent stage for the deposits in New Jersey and eastern Pennsylvania. Salisbury (1902) also mentioned that the drift beyond the terminal moraine in a few places looked much less weathered than most of the extra-morainic drift. Bayley and others (1914) divided the extra-morainic drift into "early glacial drift" that was largely till deposited during the Jerseyan stage and "extra-morainic drift" that was thought to consist of a mix of Wisconsinan and early drift. In Pennsylvania, Leverett (1934) also assigned a Wisconsinan age to the terminal moraine and the glacial drift north of it and suggested that the pre-Wisconsinan drift was deposited during the Illinoian and Kansan glaciations. MacClintock (1954) divided the Wisconsinan glacial deposits into an older drift of early Wisconsinan (Tazewell) age in northeastern New Jersey, and a younger drift of late Wisconsinan (Cary) age in northwestern New Jersey, based on the depth of carbonate leaching in glacial meltwater sediments. Crowl and Sevon (1980) suggested glacial deposits in eastern Pennsylvania consisted of the late Wisconsinan Olean drift, and that the older glacial deposits were represented by the Warrensville drift of early Wisconsinan age and the Muncy drift of Illinoian age. Cotter and others (1986) indicated the youngest glacial deposits in New Jersey and eastern Pennsylvania are of late Wisconsinan age, and are correlative with the Olean drift in Pennsylvania, and Ridge and others (1990) proposed that older weathered drift in the Delaware valley is of Illinoian age and not early Wisconsinan. Stone and others (2002) and Stanford and others (2021) also indicated that the youngest glacial deposits in New Jersey are of late Wisconsinan age, and that the two older drifts are of Illinoian and pre-Illinoian age. Ridge (2004) and Stanford and others (2021) showed that pre-Illinoian fluvial and lacustrine deposits in New Jersey have reversed magnetic polarity at two locations, and Gardner and others (1994) and Braun (2004) showed that pre-Illinoian lacustrine deposits in central and eastern Pennsylvania are also magnetically reversed,

= thousand years ago). PREGLACIAL DRAINAGE AND GEOMORPHOLOGY

indicating that the pre-Illinoian glaciation is of early Pleistocene age (older than 780 ka, ka

The primary drainage routes in the quadrangle and surrounding area were probably established well before the Pleistocene. Transverse gaps in the Highlands, including the Glen Gardner gap in the High Bridge quadrangle, are possibly relicts of an earlier ancestral Raritan River drainage system that flowed in a southeasterly direction in the middle Miocene at elevations 300 to 400 feet above modern valleys (Stanford, 1997; Witte, 1997). The Glen Gardner gap is aligned with the Delaware Water Gap in Kittatinny Mountain and with gaps in Pohatcong Mountain near Oxford, New Jersey, defining the route of this southeasterly flowing river. This route grades topographically to coastal and fluvial deposits of middle and late Miocene age in the lower Raritan basin in the New Jersey Coastal Plain (Stanford, 1997). Incision by streams in response to sustained sea-level drops in the middle and late Miocene allowed the Delaware River, through headward erosion and stream capture, to enlarge its drainage area by extending its tributaries like the Musconetcong River upvalley along the strike of less resistant rock. In response to a second sustained lowering of sea level during the early and middle Pleistocene, the drainage incised again. Along the Delaware and Raritan rivers and their larger tributaries this incision has resulted in the formation of a lower, narrower, inner valley, including Musconetcong Valley and the valleys of the South Branch and Spruce Run in the Piedmont area of the quadrangle. Pleistocene incision has also deepened valleys in the Highlands. For example, Glen Gardner gap consists of an upper, broader gap above an elevation of about 600 feet and a narrower, steeper inner valley below 600 feet through which Spruce Run flows. The upper gap was probably cut by the former southeasterly flowing ancestral river before it was captured by Delaware tributaries in the late Miocene. The inner valley was cut by Spruce Run during Pleistocene downcutting. The location of Illinoian glaciofluvial deposits in the Delaware valley (Ridge and others, 1990; Witte and Stanford, 1995) suggests that the river valleys in the study area had been lowered or nearly lowered to their present levels by the time of the Illinoian glaciation

chiefly the result of these periods of river downcutting in the late Miocene and early Pleistocene, with additional modification in the Pleistocene by periglacial and glacial erosion and deposition during glacial periods and fluvial erosion during interglacial periods. The weathering of bedrock to form saprolite and residuum during temperate and subtropical climates in the Neogene before the advent of glacial climates and during temperate interglacial periods in the Pleistocene also provided additional sediment.

The physiography of the High Bridge quadrangle reflects a composite landscape that is

The landforms of the map area can be grouped into geomorphic terrains based on their ography (fig. 1). It is convenient to do this in order to discuss the history of the landscape in reference to erosional processes and bedrock type. This methodology was applied by Germanowski (1999) to the Lehigh Valley and surrounding area in eastern Pennsylvania, which is similar to the landscape of the High Bridge Uplands consist of two terrains. Upland terrain 1 is marked by broad, relatively undissected areas of low relief (< 60 feet), underlain by gneiss and granite, with surficial materials that include weathered rock (thin to thick saprolite, scattered rubbly regolith), thin colluvium,

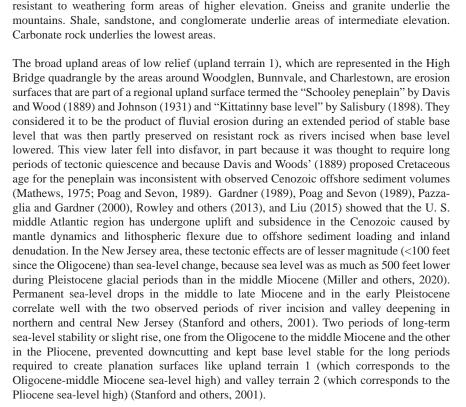

and thin patches of older drift including scattered erratics. Upland terrain 2 is marked by narrow ridges and deep narrow valleys in areas of moderate to high relief (100 to 400 feet) underlain by gneiss and granite. Surficial materials include thin to thick colluvium and thin weathered rock (saprolite and rubbly regolith). Valleys consist of three terrains. Valley terrain 1 includes modern valley floors, which are within deep (up to 100 feet), narrow, rock walled inner valleys underlain chiefly by carbonate rock. Surficial materials in this terrain include alluvium and colluvium. Valley terrain 2 is the old valley floor, which are broad areas of low relief (typically < 40 feet) and gentle slopes underlain by carbonate rock, shale, and sandstone. Surficial materials include thin (< 30 feet thick) pre-Illinoian till, till stone lag, weathered carbonate rock, thin weathered shale and sandstone, and thin colluvium. In places carbonate bedrock is deeply weathered to depths exceeding 150 feet. Valley terrain 3 includes areas of intermediate elevation consist-

ing of rolling hills and narrow ridges 100 to 200 feet higher than valley terrain 2. It is under-

lain by shale, sandstone, and conglomerate. Surficial materials include thin, patchy

pre-Illinoian till, shale-chip residuum, shale-chip colluvium, weathered shale, sandstone,

and conglomerate, and conglomerate colluvium.

Comparison between geomorphic terrains and bedrock clearly shows that rocks more

QUATERNARY GEOLOGY

The position and difference in weathering characteristics of glacial drift in New Jersey

indicate that continental ice sheets reached New Jersey at least three times (Salisbury, 1902; Stone and others, 2002). The oldest glaciation is of early Pleistocene age and covered the entire High Bridge quadrangle (fig. 4). This glaciation is represented by the Port Murray Formation (Stone and others, 2002), which includes till (unit Qpt) and meltwater deposits (Qps). It is highly and deeply weathered, and it lies on weathered bedrock. Constructional topography is not preserved, and on uplands the deposits are present only on flat to gently sloping surfaces (upland terrain 1) that are not subject to mass wasting and fluvial erosion. In lowlands they are present only on the broad old valley surfaces (valley terrain 2), as much as 120 feet above modern valley bottoms, not within the inner valleys (valley terrain 1). The age of this glaciation is uncertain. Samples collected from a silty-clay bed in a deeply weathered fluvial deposit in the Pohatcong Creek valley near Kennedys, about 8 miles southwest of Hampton, and samples of a lacustrine silt and clay at Bernardsville, about 18 miles east of High Bridge, are magnetically reversed (Ridge, 2004; Stanford and others, 2021), placing the age of the deposits older than 780 ka. If the Kennedys deposit is not outwash, but rather older alluvium laid down by Pohatcong Creek or the Delaware River, its position within the belt of older glacial drift shows that this older drift is the same age or older than the suspected outwash. An earliest Pleistocene age (between 2-2.5 Ma, Ma = million years ago) for this glaciation is suggested by pollen in lake clays of probable re-Illinoian age in Budd Lake, about 16 miles northeast of High Bridge, which include taxa that are generally considered to be of pre-Pleistocene age (Harmon, 1968), and by the similar weathering properties and topographic position of the Port Murray deposits and the Pensauken Formation, which is a preglacial fluvial deposit of Pliocene age in central New Jersey (fig. 4) (Stanford and others, 2021).

this glaciation was similar to that at present, with the exception of the inner valleys (valley terrain 1), which had not yet been cut. The height of the mountains above the old valley floors (valley terrain 2) is largely unchanged. Since the pre-Illinoian glaciation the Raritan and Musconetcong rivers and their tributaries have cut down as much as 120 feet in the older valley floor. The position of Illinoian glaciofluvial deposits in the Delaware valley, and of fluvial terrace deposits of likely Illinoian age in the Raritan valley, suggest that most of the erosion took place well before the Illinoian glaciation. The narrow, rock-walled valleys that the Raritan and Musconetcong rivers flow through support the above hypothesis. Tributary streams have likewise cut down in the uplands, which is reflected by incision and retreat of hillslopes (formation of upland terrain 2). In places streams lie as much as 200 to 300 feet below the ridge tops and upland flats of upland terrain 1.

The distribution of Port Murray till shows that the overall form of the terrain at the time of

ited a terminal moraine across the Pohatcong valley near the town of Washington (fig. 4). This glaciation is represented by the Lamington and Flanders Formations (Stone and others, 2002). These deposits are moderately weathered, and the underlying bedrock is not as weathered as it is beneath the Port Murray deposits. The deposits lie in modern valleys and constructional topography is preserved, although it has been subdued by erosion, and the drift in many places has not been eroded from hillslopes. They do not occur in the quadrangle, although the upper terrace deposits (Qtu) in the South Branch valley are fluvial deposits laid down in part during the Illinoian and may include some glacial outwash. The youngest ice sheet reached its terminus north of the quadrangle during the late Wisconsinan substage of the Wisconsinan stage; approximately 25 to 24 ka (Cotter and others, 1986; Stone and others, 2002; Stanford and others, 2021) (fig. 4). Its farthest advance is generally marked by the terminal moraine (Salisbury, 1902; Stone and others, 2002). The

deposits of this glaciation are lightly weathered, exhibit well-preserved constructional topography, generally lie on nonweathered rock, and lie in the modern drainage. Glaciofluvial sand and gravel deposits from this advance (Qwf) occur in the map area. They form terraces that flank the Musconetcong River. Nonglacial fluvial deposits in the South Branch and Mulhockaway valleys (Qtl) and alluvial fans deposited where upland streams entered lowlands (Oaf) are also mostly of late Wisconsinan age. The terrestrial (Fullerton, 1986) and oceanic (Shackleton and Hall, 1984) records show tha the growth and decay of continental ice sheets in the northern hemisphere during the Pleistocene was cyclic. In concert with the growth and decay of the Laurentide ice sheet, the

climate in the study area varied between temperate to boreal. During warm interglacials, such as the Sangamon (135 to 70 ka), the relative rate of chemical weathering increased, and an extensive cover of deeper-rooted vegetation helped reduce the rate of mass wasting. During this period thick soils were formed, and bedrock was deeply weathered, forming saprolite and decomposition residuum. In contrast, during the colder periglacial and glacial periods, there was a relative increase in the rate of physical weathering and erosion. This slowed pedogenic activity and, because of a less extensive and more shallow-rooted vegetative cover, the rate of hillslope erosion was greatly enhanced.

Braun (1989) suggested that erosion due to periglacial weathering could be on the order of

a magnitude greater than fluvial erosion in modifying the landscape during the Pleistocene Glacial and periglacial climates in New Jersey generally lasted less than 20,000 years and were marked by intense periods of physical weathering during which large volumes of colluvium were produced. Colluvium in the map area (Qcg, Qcs, Qcc, Qcal) is mostly a monolithic diamict derived from weathered bedrock (chiefly by fragmental disintegration of outcrop and regolith by frost shattering) and transported downslope largely by creep. Over time it accumulated at the base of slopes, forming an apron of thick material, and it also collected on the floors of narrow valleys and first-order drainage basins. In places it is greater than fifty feet thick and it covers large parts of the landscape. Rates of sedimentation appear to be high, typically overwhelming the capacity of the streams to remove sediment. During periods of temperate climate, sediment production by periglacial processes decreases, resulting in an increased rate of fluvial erosion. However, the total volume of material removed by fluvial erosion (gullying of slopes, incision of colluvium and alluvial fans, sapping by springs, lateral erosion of toe slopes) during temperate periods was less than the volume moved downslope during periglacial periods.

Following the late Wisconsinan glaciation, climate warmed and forest grew, limiting further erosion. A 6-foot core of peat and organic silty clay from a wetland (Qs) known as Bog Meadow on Musconetcong Mountain near Charlestown that formed when an upland valley was dammed by colluvium during the late Wisconsinan records the postglacial vegetation changes between 18 and 13 ka (Russell and Stanford, 2000). During cold climate from 18 to 14 ka the vegetation was patches of spruce and pine in an open grassland. After 14 ka warming caused a change to a deciduous forest dominated by oak. The transition from grassland to forest stabilized the land surface and allowed streams to erode into colluvium and terrace deposits, forming present-day floodplains (Qal) in the Holocene. SURFICIAL DEPOSITS

Surficial materials in the High Bridge quadrangle include alluvium, swamp deposits, colluvium, glacial deposits, and weathered bedrock. They are defined by their lithic characteristics (composition, texture, color, and structure) and bounding discontinuities. Ion-Glacial Deposits

Stream deposits (alluvium, stream-terrace deposits, and alluvial-fan deposits)

Alluvium (Qal) is chiefly of Holocene age and includes both channel (sand and gravel) and overbank (sand and silt) sediment laid down by streams in sheet-like deposits on the floors of modern valleys. In some upland valleys it includes cobble and boulder lags formed by the washing away of fine sediment from colluvium and weathered bedrock (fig. 5). Stream terrace deposits include both channel and floodplain sediment. They include a lower terrace (Otl, fig. 6) that lies 5 to 10 feet above the modern floodplain and, in the Mulhockaway Creek basin and along the South Branch, an upper terrace (Otu) that lies 10 to 20 feet above the modern floodplain. Along the Musconetcong River the lower terrace is inset into the late Wisconsinan glaciofluvial terrace and so is of postglacial age. In the Raritan basin the lower terraces are mostly of late Wisconsinan age, because downstream in the Raritan valley they grade to late Wisconsinan glaciofluvial deposits in the Manville and Plainfield area (fig. 4) (Stone and others, 2002). The lower terraces in the Raritan basin are nonglacial because the South Branch did not carry any late Wisconsinan glacial sediment, only clean lake outflows from glacial Budd Lake.

Upper terrace deposits along the South Branch and Mulhockaway Creek consist of moderately weathered sand and gravel. The degree of weathering is similar to that of glacial deposits of Illinoian age. At its maximum position the Illinoian glacier deposited a small glaciofluvial plain in the headwaters of the South Branch near Flanders, 16 miles northeast of High Bridge (fig. 4) (Drakes Brook outwash of Stone and others, 2002). Some of this glaciofluvial sediment may have been carried into the High Bridge quadrangle and deposited in the upper terrace, but there is no glaciofluvial terrace along the South Branch between High Bridge and the Flanders area, suggesting that little sediment was transported beyond the Drakes Brook deposit. This indicates that the upper terrace is chiefly nonglacial alluvium laid down during the Illinoian and possibly during the early and middle Wisconsinan. Downstream in the Raritan valley the upper terrace is inset by late Wisconsinan glaciofluvial deposits in the Manville area, indicating that the upper terrace is of pre-late Wisconsinan age (Stone and others, 2002). Upper terraces along Mulhockaway Creek are locally derived from weathered gneiss and conglomerate with minor contributions from pre-Illinoian till.

Alluvial-fan deposits (Qaf) are scattered throughout the quadrangle where streams emerge from uplands into valleys and lowlands. Their surfaces are entrenched by the modern drainage. These erosional channels show that the fans are not presently forming and likely were deposited primarily during cold climate in the late Wisconsinan.

accumulated largely in early postglacial time before the Holocene. Hillslope sediment

Organic deposits

part be older nonglacial fluvial deposits.

Musconetcong and South Branch valleys. Weathered Bedrock

Qwcb), quartzite (included with Qwg), and conglomerate (Qwc). Weathered gneiss (Qwg) consists chiefly of saprolite, grus and rock rubble. Structured and deeply etched.

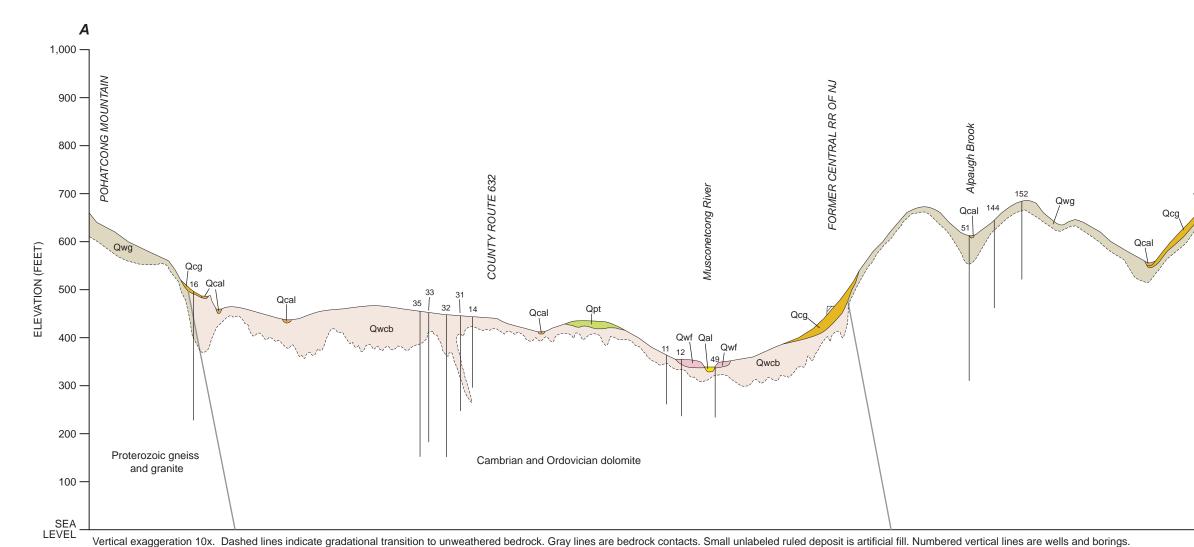

cobbles, soil, and a few glacial erratics.

Weathered conglomerate (Qwc) consists of decomposition residuum and some saprolite containing unweathered to lightly weathered cobbles and pebbles of quartzite, conglomerate, sandstone, and shale. Weathering extends deeply in the subsurface along fractures and

modern floodplain.

silt. and clav.

Swamp and bog deposits (Qs) occur in a wetland known as Bog Meadow on Musconetcong Mountain. Bog Meadow occupies an upland valley dammed by colluvium that aggraded in a narrow part of the valley at the south end of the wetland. Peat and organic silt and clay in the deposit were sampled in a 6-foot core and yielded radiocarbon dates of 11,480±60 yrs BP (GX-22772 AMS) (calibrating to 13.2-13.5 ka two-sigma uncertainty, 13.4 ka median age, using the Stuiver and others (2022) calibration program) in peat at a depth of 1.2 feet, 12,490±70 yrs BP (GX-22027 AMS) (14.3-15.0 ka; 14.7 ka) in organic silty clay at 1.7 feet, 15,160±70 yrs BP (GX-22773 AMS) (18.3-18.7 ka; 18.5 ka) in organic silty clay at 5.1 feet, and 13,580±80 yrs BP (GX22028 AMS) (16.1-16.6 ka; 16.4 ka) in organic sand at 5.7 feet. The lowermost date in organic sand is younger than the overlying date in silty clay. This age reversal may be because the permeable sand allowed younger organic material carried by groundwater from above to enter the sample. These dates indicate that the organic deposits

Hillslope deposits include colluvium (Qcg, Qcs, Qcc) and undifferentiated alluvium and colluvium (Qcal). These deposits are derived from underlying and upslope materials transported downslope by soil creep, solifluction, earth and debris flows, and rock fall. Colluvium in the quadrangle is widespread and is derived from weathered gneiss and granite (Qcg, figs. 7, 8, 9), weathered shale and sandstone (Qcs), and weathered conglomerate (Occ). It typically forms a monolithic diamict that mantles most slopes and forms thick aprons of material on their lower parts. In places, distal parts of these aprons on toe slopes consist of silty clay sediment derived from seepage erosion of coarser colluvium upslope (fig. 9). Colluvium also collects in small first-order drainage basins in upland areas. In places colluvium includes thin beds and lenses of sorted, stratified sheet- and rill-wash sand and gravel (fig. 8). Undifferentiated alluvium and colluvium (Qcal) consists of a mixture of alluvium and colluvium that has accumulated in narrow valleys in the upper parts of drainage basins. These deposits in places also include cobble and boulder lags formed by the washing away of fine sediment, and the toe slopes of small colluvial aprons. In places, unweathered to lightly weathered colluvium of Wisconsinan age overlies weathered colluvium of presumably pre-Wisconsinan age, and a truncated reddish soil marks the contact between the two (fig. 7). This stratigraphy supports the hypothesis that colluviation is cyclic and occurs largely during periods of cold climate and that slopes are largely stable

Glacial Deposits

Till is a poorly sorted, nonstratified to very poorly stratified mixture ranging in grain size from clay to boulders that was deposited directly by or from a glacier. In the High Bridge quadrangle, till is mapped as the Port Murray Formation, till facies (Qpt, fig. 10). It is highly weathered, has a clayey matrix, is oxidized and leached of carbonate material, lies on weathered bedrock, and is only found in places where it has been protected from erosion, generally 60 to 100 feet above modern valley bottoms where it is typically found on the old valley floors of the Raritan and Musconetcong valleys, and to a lesser extent on flat upland surfaces. It was formerly more extensive. In places it is represented by a lag consisting of pebbles and cobbles of quartzite, chert, and quartzose siltstone that were left when the till was eroded. In most places the till appears to be in place, although extensive surface and near-surface modification by cryoturbation, bioturbation, and minor colluviation is

Sediment carried by glacial meltwater streams was laid down at and beyond the glacier margin in glaciofluvial deposits of late Wisconsinan age in the Musconetcong Valley (Qwf) and of pre-Illinoian age in the South Branch valley (Qps). The late Wisconsinan deposits are part of the Rockaway Formation (Stone and others, 2002) and consist of interbedded, horizontally stratified beds of sorted gravel, sand, and silt. They form terraces of lightly weathered gravel and sand that lie as much as 20 feet above modern floodplain. These terraces are remnants of an outwash plain that extended downstream from the terminal

A high standing terrace (Qps) along the South Branch just south of Clinton probably represents glacial outwash laid down from a pre-Illinoian recessional position. This deposit lies as much as 100 feet above the modern river and consists of weathered sand and gravel. Based on its advanced state of weathering, height above the modern drainage, and similarity to other high-standing weathered fluvial deposits along the Musconetcong, Raritan, and ers (Witte and Stanford, 1995; Stone and others, 2002) it is presumed to h been laid down by meltwater streams during the pre-Illinoian glaciation in the early Pleistocene. Because the upper parts of these stratified deposits are weathered to a round-stone diamict, they are difficult to distinguish from the Port Murray till in places. They may in

Due to the scant distribution and poor preservation of the pre-Illinoian deposits, and lack of recognizable recessional deposits, the history of the pre-Illinoian deglaciation is uncertain. If deglaciation proceeded as it did in the late Wisconsinan, then ice-recessional positions may have been marked by the heads-of-outwash of glaciofluvial deposits laid down in the

Weathered bedrock consists of saprolite, decomposition and solution residuum, and rock complex history of weathering and erosion where the climate varied between cold conditions during glacial and periglacial periods to temperate and subtropical conditions during preglacial and interglacial periods. Weathered bedrock materials in the quadrangle were chiefly derived from gneiss (Qwg), shale and sandstone (Qws), dolomite and limestone

saprolite extends deeply into bedrock along joints, fractures and foliations. Grus and rock rubble generally form a surface cover of varying thickness. Bedrock outcrops are few and generally lie only along ridge crests, very steep hillslopes, and deeply cut streambanks. Dutcrops form tors, subtors, and disorganized masses of irregularly spaced joint-block

Weathered shale and sandstone (Qws) consist chiefly of decomposition residuum (Richmond and others, 1991), and shale-chip rubble. Bedrock does not generally crop out. he surface of the weathered material is a mix of shale chips, blocky sandstone pebbles and

others, 1991), and karst-fill materials. Weathering extends deeply in the subsurface along fractures, joints, solution openings, and along bedding. In many places the weathered bedrock is in sharp contact with nonweathered bedrock. Bedrock outcrops are widely scattered, most are marked by a pile of irregularly-shaped blocky boulders along the crest of a ridge or on a hillslope. The rock surface is very irregular and deeply etched along joints

joints. In places thick deposits of cobbly clay saprolite have formed. DESCRIPTION OF MAP UNITS

Map units denote unconsolidated materials more than 5 feet thick. Color names are based on Munsell Color Company (1975) and were determined from naturally moist samples. ARTIFICIAL FILL-Excavated rock, gravel, sand, silt, and manufactured naterials (cinders, ash, brick, glass, concrete, asphalt) emplaced by humans. Color of fine sediment is variable but generally gray, brown, and black. As much as 60 feet thick. Many small areas of fill, particularly along streams and in urban

> ALLUVIUM—Stratified, moderately to poorly sorted sand, pebble-to-cobble upland valleys. Fine sediment is brown, gray, yellowish brown and reddish brown. As much as 20 feet thick. Includes planar to cross-bedded gravel and sand in channel deposits, and cross-bedded and rippled sand, massive and by and interlayered with thin organic material and colluvium.

ALLUVIAL-FAN DEPOSITS—Stratified, moderately to poorly sorted, sand, pebble-to-cobble gravel, minor boulder gravel, and minor clay and silt. Color of fine sediment is brown, yellowish brown, and gray. As much as 20 feet thick. Includes massive to plane-bedded sand and gravel and minor cross bedded channel-fill sand. Bedding dips as much as 30 degrees toward the trunk valley. Locally interlayered with unstratified, poorly sorted, sandy-silty to sandy gravel. Forms fan-shaped deposits entrenched 5 to 10 feet by present-day channels.

colluvium as in units Qcg, Qcs, and Qcc. As much as 20 feet thick. OWER TERRACE DEPOSITS—Stratified well to moderately sort massive to laminated, and minor crossbedded fine-to-coarse sand and silt overlying and interbedded with massive to horizontally bedded cobble and pebble gravel and pebbly sand. Fine sediment is brown, yellowish brown, and reddish

LATE WISCONSINAN GLACIOFLUVIAL DEPOSITS-Stratified, well to moderately sorted sand, cobble to pebble gravel, and minor silt deposited by meltwater in Musconetcong Valley. Fine sediment is yellowish brown, brown, and gray. As much as 30 feet thick. Includes massive to horizontally bedded and imbricated coarse gravel and sand, and planar to tabular and trough cross bedded, fine gravel and sand in bars, and channel lag deposits with minor cross bedded sand in channel-fill deposits. Overbank deposits of massive to laminated fine

GNEISS COLLUVIUM—Massive to crudely layered, slightly compact, poorly sand and clayey sandy silt, containing as much as 60 percent lightly to moderately weathered angular to subangular cobbles, pebbles, and boulders of gneiss and foliated granite. As much as 50 feet thick. Matrix consists of a varied mixture of quartz sand, weathered feldspar, mica, amphibole, heavy minerals,

SHALE AND SANDSTONE COLLUVIUM—Crudely to moderately layered, ncompact, poorly sorted light yellowish brown, brownish yellow, and light olive-brown silty sand and clayey silt, containing as much as 60 percent lightly to moderately weathered angular to subangular shale chips, tabular pebbles and cobbles of siltstone and sandstone. As much as 30 feet thick. Matrix consists of a varied mixture of rock fragments, quartz sand, silt, and clay. ONGLOMERATE COLLUVIUM—Massive to crudely layered, slightly compact, poorly sorted, reddish brown to yellowish brown silty clay to silty

and pebbles of gray, reddish brown, and brown quartzite and quartzite conglomerate. As much as 20 feet thick. UPPER TERRACE DEPOSITS—Stratified, well to moderately sorted, sand, ilt, and clay overlying and interbedded with massive to horizontally bedded pebble and cobble gravel. Fine sediment is yellowish brown, brown, and reddish

clayey sand containing as much as 20 percent subangular to subrounded cobbles

brown. As much as 20 feet thick. Forms terraces with surfaces 10 to 20 feet above the modern floodplain. Also in an abandoned meander channel of the South Branch inset into gneiss bedrock southeast of Mariannes Corner, about 15 feet above the modern floodplain. PORT MURRAY FORMATION, TILL FACIES—Deeply weathered, compact, massive to crudely layered reddish yellow, strong-brown, yellowish brown,

reddish brown, and weak-red sandy silt and clayey silt that typically contains 2 to 5 percent gravel. As much as 30 feet thick. Gravel consists of pebbles and cobbles of quartzite, gneiss, quartzose sandstone and siltstone, shale, carbonate rock, and chert, and a few boulders of quartzite and gneiss. Gneiss clasts have thick weathering rinds or are completely decomposed; carbonate clasts are fully decomposed. Quartzite, sandstone, and chert pebbles and cobbles have pitted surfaces and thin weathering rinds. Matrix contains clay, quartz weathered rock fragments, minor weathered mica, and few heavy minerals. Subvertical joints are poorly to moderately developed to depths exceeding 10 feet. Clasts and joints are commonly coated with red iron and black iron-manganese oxide.

PORT MURRAY FORMATION, STRATIFIED FACIES-Brownish yellow, yellowish brown medium-to-coarse sand and pebble-to-cobble gravel, poorly stratified to massive. Clasts are subrounded to well-rounded gneiss, quartite chert, quartzose sandstone and siltstone. Gneiss clasts are decomposed to depths exceeding 15 feet. Quartizte and chert clasts have weathering rinds <0.1 inch thick and are coated with a brown iron-manganese stain. Sandstone and quartzite clasts have pitted surfaces. Deposit caps a rock-cut terrace about 80 to 100 feet above the modern South Branch floodplain south of Clinton. WEATHERED GNEISS-Massive to layered, noncompact to compact, brown,

yellowish brown, strong brown, white, and red silty clayey sand to sandy silty clay saprolite consisting of clay, quartz, minor mica and heavy minerals; and white to yellowish brown sandy grus with angular pebbles and cobbles; and angular cobble to boulder rock rubble. As much as 100 feet thick. Includes thin stony and blocky colluvium on hillslopes, and a bouldery to cobbly mantle of angular to subangular gneiss and granite on very gentle hillslopes; as much as 10 feet thick. Weathered zone grades downward through a bouldery zone of joint blocks into underlying unweathered bedrock, and extends deeply along joints, fractures, and bedrock layers. In the subsurface, joint blocks and rock rubble typically have thick weathering rinds. Qwgt indicates areas where weathered material is thin or absent and fractured-rock rubble with scattered outcrop is abundant.

WEATHERED SHALE AND SANDSTONE—Massive to layered, noncompact to slightly compact, yellowish brown, brown, reddish brown silty clay to sandy silt with as much as 50% shale chips and subangular pebbles and cobbles of sandstone and siltstone. As much as 20 feet thick. Locally includes thin (<10 feet) colluvium on hillslopes. Weathered zone typically grades downward through a zone of fractured rock into underlying unweathered bedrock.

Qwcb WEATHERED CARBONATE ROCK-Massive, compact, light-red, red, reddish yellow, strong-brown, yellowish brown, yellow clay and silty clay solution residuum of clay, quartz, and iron oxide; generally with less than 5 percent chert, vein quartz and minor quartzite. Thickness is highly variable, typically less than 15 feet but locally as much as 150 feet. Locally includes thin colluvium (<5 feet) on gentle hillslopes. Also may include sand, gravel, silt, and clay washed into sinkholes and solution cavities from overlying colluvi alluvial, and glacial sediment. Weathered zone typically ends at an abrupt, very irregular contact with unweathered bedrock and also extends deeply along joints and fractures. Qwcbt indicates areas where weathered material is thin or absent

WEATHERED CONGLOMERATE—Yellowish brown, reddish brown sandy silty clay to clayey silty sand containing 10 to 50 percent subangular to subrounded pebbles and cobbles of gray, brown, and red quartzite, quartzite conglomerate, shale, and sandstone. As much as 70 feet thick. Locally includes thin colluvium less than 5 feet thick. Weathered zone typically grades downward through a zone of fractured rock into underlying unweathered bedrock. Survey, Open File Map OFM 15C, 3 plates, map scale 1:48,000. EXPLANATION OF MAP SYMBOLS ——— Contact—Contacts of units Qal, Qaf, Qs, Qcal, Qtl, and Qtu are generally well-defined by landforms and are based on 1:12,000 stereo aerial photographs

and LiDAR imagery. Contacts of other units are based on landforms and field observations and are gradational, feather-edged, or approximate. ⁴⁷• Well with log in table 1—Location accurate to within 500 feet.

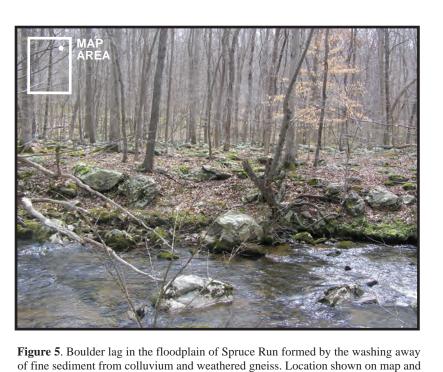

figure 5 • Photograph location

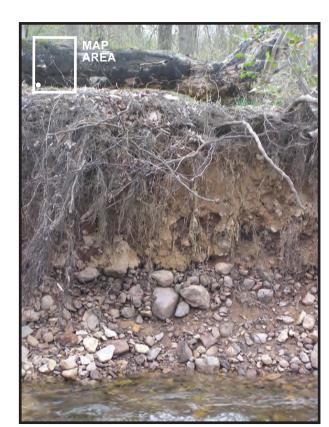

Bedrock outcrop—Many small outcrops are not shown. Refer to Monteverde and others (2015) and figure 3 for the location of these small outcrops. Quarry—Bedrock exposed in quarry or pit.

/ Striation—On quartzite bedrock. Records flow direction of the pre-Illinoian glacier. Reported by H. B. Kummel on unpublished field maps on file at the N. J. Geological and Water Survey (circa 1890) but no longer exposed.

○ Solution basin—Formed by dissolution of underlying carbonate bedrock. Open line indicates semi-enclosed basins with an opening facing downslope. Dashed lines adjacent to basins west of Clinton mark raised rims on the basin perimeters. The rims suggest that these basins may be partly of thermokarst origin.

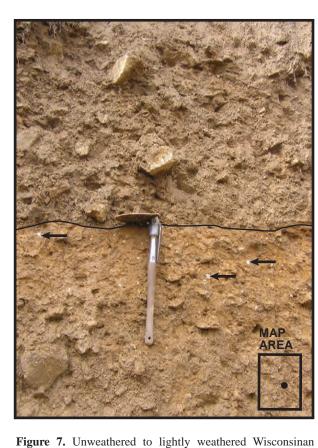

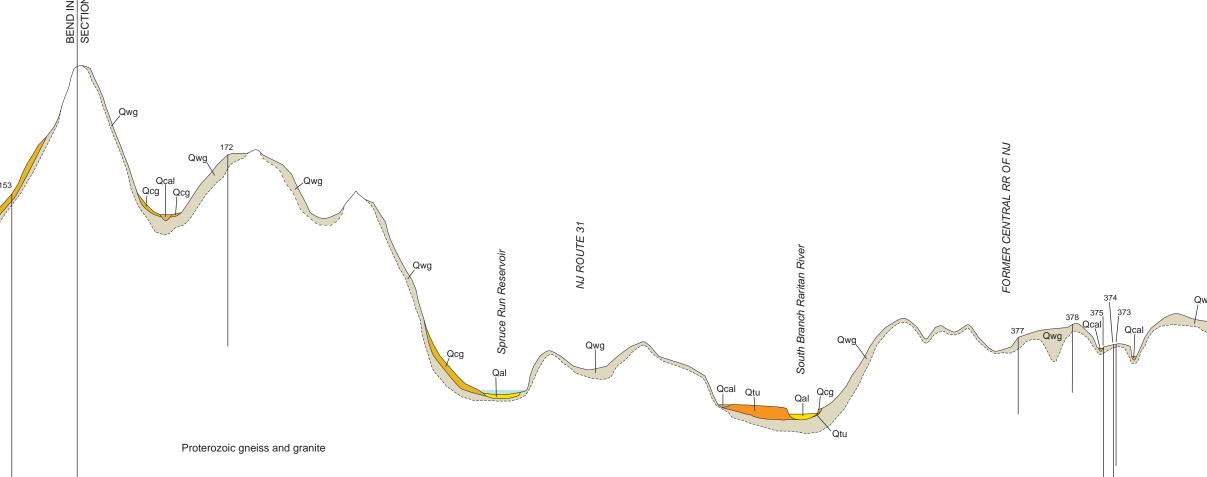

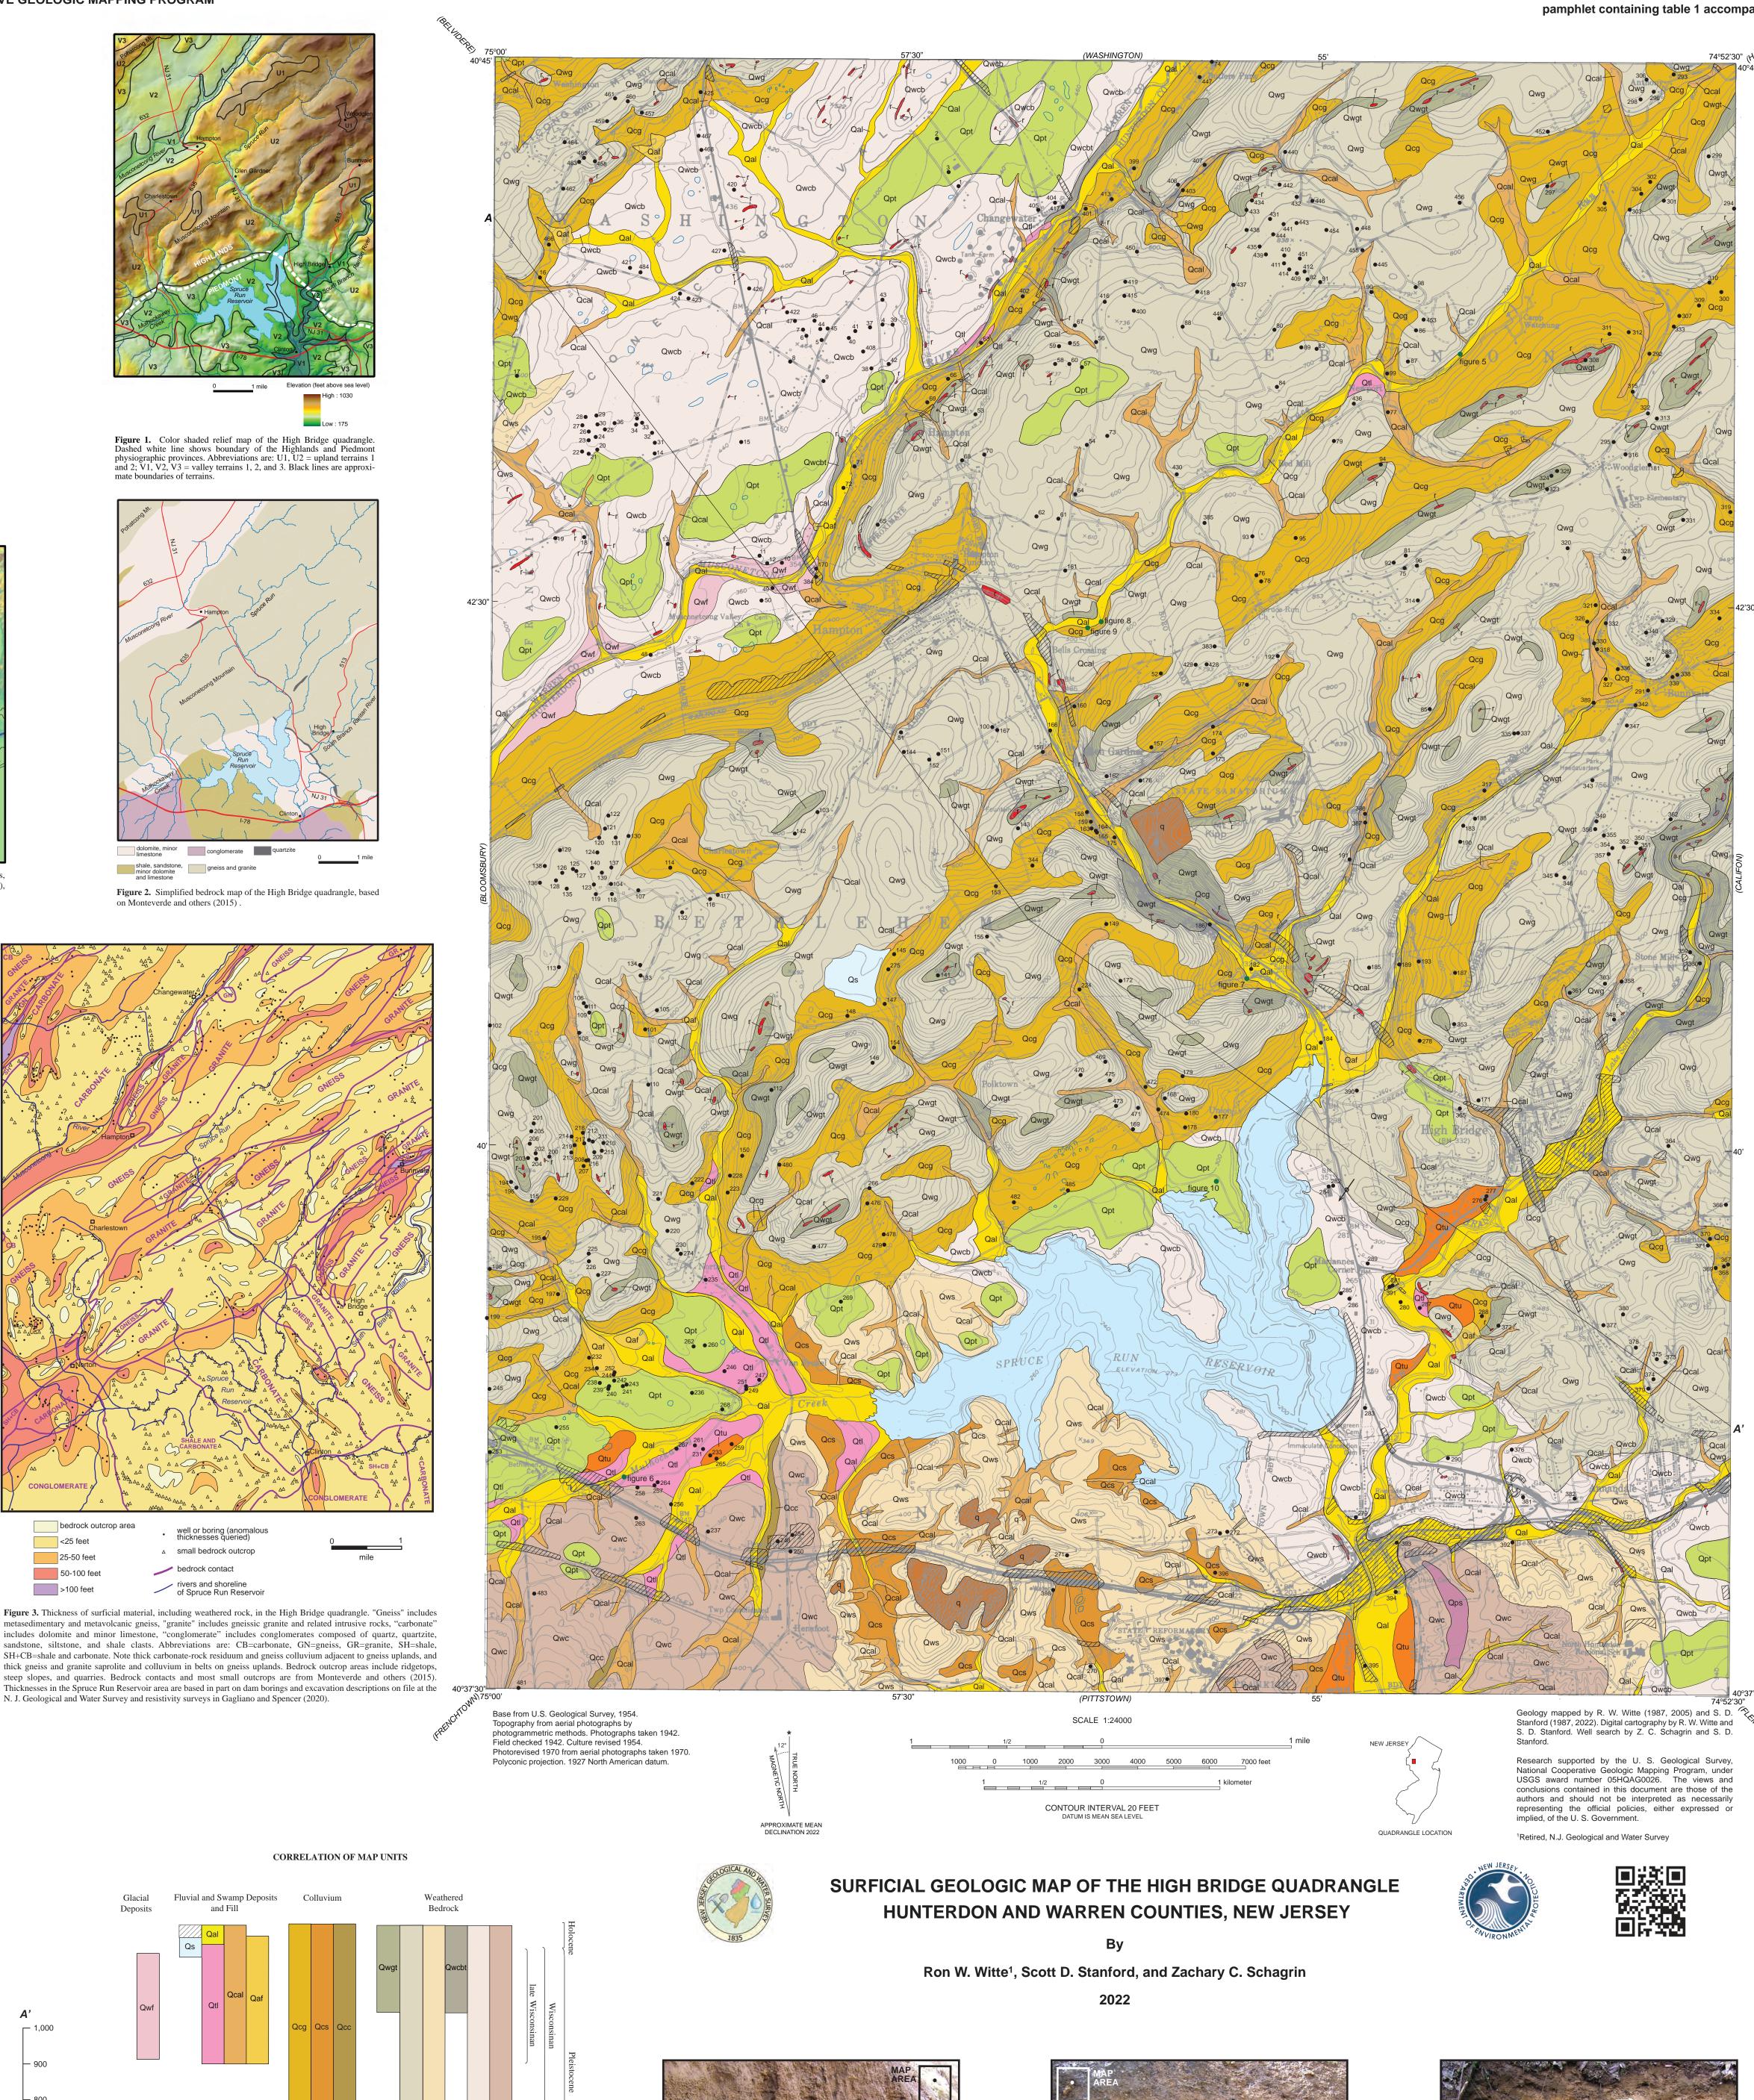

inset. Photograph by S. Stanford.

Figure 6. Cobble gravel in lower terrace deposit along Mulhockaway Creek. Height of streambank is about 6 feet. Fine sand and silt overbank deposits overlie the gravel. Location shown on map and inset. Photograph by S. Stanford.

colluvium (above line) overyling soil developed in pre-Wisconsinan weathered colluvium (below line). White spots (marked by black arrows) are decomposed gneiss pebbles in the weathered colluvium. Location shown on map and inset. Photograph by S. Stanford.

to lightly weathered. Location shown on map and inset. Photograph by S. Stanford.

Surficial Geology of the High Bridge Quadrangle Hunterdon and Warren Counties, New Jersey

New Jersey Geological and Water Survey Open-File Map OFM 145 2022

Pamphlet with Table 1 to accompany map

Table 1. Records of selected wells in the High Bridge quadrangle. Well number is the number shown on the geologic map. Permit number is a unique identifier issued by the N. J. Department of Environmental Protection. All are prefixed by "24-" except those of the form "44-xxx". Well locations are based on tax parcels as reported on well permits and are generally accurate to within 200 feet of actual location. Depths and static water level are in feet below land surface. Discharge is in gallons per minute. Depths, static water level, discharge, and log are as reported on driller's well record. No entry indicates value not reported on well record. Query indicates information not readable on well record. Brackets indicate inferences by authors.

Well Number	Permit Number	Total Depth	Casing Depth	Static Water Level	Discharge	Driller's Log
